A stabilizing effect of advection on planar interfaces in singularly perturbed reaction-diffusion equations

Paul Carter*

March 25, 2024

Abstract

We consider planar traveling fronts between stable steady states in two-component singularly perturbed reaction-diffusion-advection equations, where a small quantity $\delta^2$ represents the ratio of diffusion coefficients. The fronts under consideration are large amplitude and contain a sharp interface, induced by traversing a fast heteroclinic orbit in a suitable slow-fast framework. We explore the effect of advection on the spectral stability of the fronts to long wavelength perturbations in two spatial dimensions. We find that for suitably large advection coefficient $\nu$, the fronts are stable to such perturbations, while they can be unstable for smaller values of $\nu$. In this case, a critical asymptotic scaling $\nu \sim \delta^{-4/3}$ is obtained at which the onset of instability occurs. The results are applied to a family of traveling fronts in a dryland ecosystem model.

1 Introduction

We consider two-component reaction-diffusion-advection equations of the form

$$
\begin{align*}
U_t &= \Delta U + F(U, V; \mu) \\
V_t &= \frac{1}{\delta^2} \Delta V + G(U, V; \mu) + \nu V_x
\end{align*}
$$

(1.1)

where $U(x, y, t), V(x, y, t) : \mathbb{R}^2 \times \mathbb{R} \to \mathbb{R}$, $F$ and $G$ are smooth functions, and $\mu \in \mathbb{R}^m$ denotes a collection of system parameters. We assume that (1.1) is singularly perturbed, with $0 < \delta \ll 1$. The advection coefficient $0 \leq \nu < \infty$ is arbitrary. We consider planar interfaces between spatially homogeneous stable steady state solutions $(U, V)(x, y, t) = (U^\pm, V^\pm)$ of (1.1). The planar interfaces manifest as traveling wave solutions $(U, V)(x, y, t) = (u_h, v_h)(\xi), \xi = x - ct$, which propagate with constant speed $c$ in the $x$-direction, and are constant in the $y$-direction, and asymptotically approach the steady states $\lim_{\xi \to \pm\infty} (u_h, v_h)(\xi) = (U^\pm, V^\pm)$.

Reaction-diffusion-advection systems arise in models of diverse phenomena such as pattern formation in mussel beds [7] and plankton [41], fog and wind induced vegetation alignment [9], disease spread [28], and population dynamics [15]. Here, we are primarily motivated by the phenomenon of desertification fronts in water-limited ecosystems [56], in which the bare-soil state slowly invades a vegetated state, resulting in (typically irreversible) desertification [30, 53], and similarly the reverse mechanism of vegetation fronts, in which vegetation invades a bare soil state. Instabilities in the resulting planar interface between vegetation and bare soil have been linked to spatial pattern formation [3, 14, 25]; see also §6. Similar interfaces also appear in savanna/forest ecosystems, cloud formation, salt marshes, and other applications [6, 39].

Our aim is to examine the effect of the advection term $\nu V_x$ on the stability of such an interface in two spatial dimensions. In systems of the form (1.1), the relation between diffusive and advective dynamics is known to impact...
the stability of planar stripes and periodic patterns [49, 50], and in particular the presence of advection can have a stabilizing effect in the direction along the stripe [36]. We aim to explore the stabilizing effect of advection, focussing on long wavelength instabilities in the case of a single planar interface between stable steady states. We note that such interfaces in the class of equations (1.1) were previously studied in the absence of advection, i.e. \( \nu = 0 \), on infinite [14] and cylindrical domains [51, 52].

In the context of the motivating example of vegetation pattern formation in dryland ecosystem models, the quantities \( U \) and \( V \) represent interacting species and/or resources, for example \( U \) may represent vegetation biomass, and \( V \) represents water availability. In such models, it is natural to have widely separated diffusion coefficients due to the differing length and/or time scales on which water is transported and on which different vegetation species evolve [44].

In this setting, the advection term represents a slope in the topography, leading to downhill flow of water, and thus an anisotropy in the system. Observations suggest that the absence of advection (that is, flat terrain) lead to spotted and/or labrynthine patterns, whereas on sloped terrain vegetation may align in bands, consisting of interfaces alternating between vegetated and desert states [4, 16, 17, 27, 40, 54]. These interfaces align perpendicular to the slope, suggesting that the downhill flow of water prescribes a preferred orientation of the interface [42]. In [14] it was shown that such planar interfaces are unstable in many ecosystem models in the absence of advection, and it is the goal of this work to examine the effect of advection on the (in)stability of such interfaces. In particular, we demonstrate that sufficiently large advection has a stabilizing effect on interfaces in two spatial dimensions, with respect to long wavelength perturbations in the \( y \)-direction, transverse to the direction of propagation.

In the spirit of [14], our results are framed in the context of a geometric singular perturbation analysis of the traveling wave equation associated with (1.1), under suitable assumptions about the underlying geometry of the system. The novel contribution of the current study is the inclusion of the advection term; the coefficient \( \nu \) can be small or large relative to the small parameter \( \delta \), naturally leading to a three timescale system. Systems with more than two timescales, and potentially multiple interacting singular limits, are responsible for complex dynamics in many applications [13, 18, 33, 37] and present challenges in the direct use of geometric singular perturbation methods, which are typically formulated for two-timescale systems. However, for systems with multiple small (or large) parameters, geometric singular perturbation methods can be used to identify critical overlapping scaling regimes, analyze the system separately in each regime, and piece the analyses together to obtain a complete picture of the dynamics in the presence of multiple singular limits [37]. In particular, in the system (1.1), using a formal asymptotic approach inspired by geometric singular perturbation methods, we are able to obtain a simple explicit criterion for (in)stability of planar interfaces, depending on the relative scaling of \( \nu, \delta \), and we identify a potential onset of (in)stability at a critical scaling \( \nu \sim \delta^{-4/3} \). The results can be easily applied to fronts in reaction-diffusion-advection models, and we demonstrate the applicability of the results to a dryland ecosystem model in §5.

We note that the results also apply to systems of the form

\[
\begin{align*}
U_t &= \Delta U + F(U,V;\mu) + \nu_1 U_x \\
V_t &= \frac{1}{\delta^2} \Delta V + G(U,V;\mu) + \nu_2 V_x
\end{align*}
\]  

for arbitrary advection coefficients \( \nu_i \in \mathbb{R} \). By shifting to a traveling coordinate frame, and reversing the spatial variable \( x \) if necessary, this system can be transformed to (1.1), defining \( 0 \leq \nu = |\nu_1 - \nu_2| < \infty \) as the differential flow [45, 49]. Additionally, we note that the reaction terms \( F \) and \( G \) in (1.1) do not depend explicitly on \( \delta \) or \( \nu \). While one could consider such a dependence in a given model with explicit reaction terms, we will see that the behavior of this system depends critically on certain relative scalings between the parameters \( \delta \) and \( \nu \). To avoid additionally tracking these scalings within the reaction terms themselves throughout the various scaling regimes, for simplicity we assume they are independent of \((\delta, \nu)\).
2 Setup

2.1 Traveling wave formulation

To capture traveling front solutions which propagate in the direction determined by the advection term, we move into a traveling coordinate frame \( \xi = x - ct \) and obtain the system

\[
\begin{align*}
U_t &= U_{\xi\xi} + U_{yy} + cU_\xi + F(U,V) \\
V_t &= \frac{1}{\delta^2}(V_{\xi\xi} + V_{yy}) + (\nu + c)V_\xi + G(U,V)
\end{align*}
\]  

(2.1)

where we drop the explicit dependence on the system parameters \( \mu \). We search for stationary solutions \((U,V)(\xi, y, t) = (u, v)(\xi)\), which are constant in the \( y \)-direction, and thus propagate with constant speed \( c \) in the \( x \)-direction. This results in the traveling wave ODE

\[
\begin{align*}
0 &= u_{\xi\xi} + cu_\xi + F(u, v) \\
0 &= v_{\xi\xi} + \delta^2(\nu + c)v_\xi + \delta^2 G(u, v).
\end{align*}
\]  

(2.2)

The system (2.2) can then be written as the first order system

\[
\begin{align*}
u_\xi &= p \\
p_\xi &= -cp - F(u, v) \\
q_\xi &= -\delta^2(\nu + c)q - \delta G(u, v).
\end{align*}
\]  

(2.3)

where the homogeneous rest states \((U^\pm, V^\pm)\) of (1.1) correspond to fixed points \( P^\pm = (U^\pm, 0, V^\pm, 0) \) of (2.3), and traveling fronts between the rest states \((U^\pm, V^\pm)\) correspond to heteroclinic orbits between the fixed points \( P^\pm \) in (2.3).

To analyze traveling front solutions in (2.2), we use geometric singular perturbation theory [24]. Throughout, we assume that \( \delta \ll 1 \) is a small parameter, but the parameter \( \nu \) can be small or large. Thus in the regime \( \delta \ll 1 \), this system can have up to three timescales, determined by the relation between the two parameters \( \nu, \delta \), and we must therefore separate the analysis of (2.2) into cases, depending on the relative size of the parameters \( \nu, \delta \).

The following singular perturbation analysis distinguishes between 3 cases, depending on which parameter is used as the primary singular perturbation parameter, and we describe the slow-fast structure of traveling fronts in each of these regions for sufficiently small \( 0 < \delta \ll 1 \). In the weak advection regime \( 0 \leq \nu \leq O(\delta^{-1}) \), \( \delta \) serves as the timescale separation parameter, while in the strong advection regime \( \nu \geq O(\delta^{-2}) \), the quantity \( \varepsilon := \nu^{-1} \ll 1 \) is taken as the timescale separation parameter. In the intermediate regime \( O(\delta^{-1}) \leq \nu \leq O(\delta^{-2}) \), the advection-diffusion coefficient “ratio” \( r := \delta^2\nu \) is taken as the primary singular perturbation parameter. By combining the results in these regions, we are able to describe the slow-fast structure of traveling front solutions for each \( (\nu, \delta) \) satisfying \( \nu \geq 0, 0 < \delta \leq \delta_0 \) for some \( \delta_0 > 0 \); see Figure 1 and §2.3. Due to the appearance of the \( \delta^2\nu \) coefficient in (2.2), the quantity \( r \) will in fact play an important role throughout the three regimes.

In each regime, the set \( S = \{ F(u, v) = 0 \} \) organizes the dynamics, as this set helps define the critical manifold(s) which appear in the slow-fast formulation of the traveling wave problem. Generally, on a given compact set, away from points where \( F_u = 0 \), \( S \) is formed by the union of a finite number of branches \( S_j, j = 1, \ldots, N \), which can be written as graphs \( u = f_j(v) \) satisfying \( F(f_j(v), v)) = 0 \) for \( v \in I_j \), where \( I_j \) is an interval. Among these, we identify those branches which contain the steady states \((U^\pm, V^\pm)\); in particular, we denote by \( f^\pm \) the functions, defined on intervals \( v \in I^\pm \), which define the graphs corresponding to the two branches \( S^\pm \) of \( S \) satisfying \( f^\pm(V^\pm) = U^\pm \), and we let \( F_u^\pm \) denote \( \frac{\partial F}{\partial u}(U^\pm, V^\pm) \), etc. Independent of the specific parameter regime, we make the following basic assumptions regarding the steady states \((U^\pm, V^\pm)\).
Figure 1 – Shown is a schematic of the different scaling regimes considered. The dashed and solid curves represent the boundary curves $\nu = \frac{\delta_0}{\delta}$ and $\nu = \frac{\delta}{\delta_0}$, respectively, as described in §2.3. The weak advection (W), intermediate (I), and strong advection (S) regimes are labeled accordingly.

Figure 2 – (Left) The steady states $(U^\pm, V^\pm)$ and the branches $S^\pm$ of the nullcline $F(U, V) = 0$. (Right) Schematic of a traveling front solution $(u_h, v_h)(\xi)$ with a single sharp interface.

Assumption 1. *(Steady states)*

(i) There exist two homogeneous steady states $(U^\pm, V^\pm)$ which are stable as solutions of (1.1) for $0 < \delta \ll 1$ and all $\nu \geq 0$. In particular, we assume (see Appendix A)

\[ F_u^\pm < 0, \quad G_v^\pm < 0, \quad F_u^\pm G_v^\pm - F_v^\pm G_u^\pm > 0. \quad (2.4) \]

(ii) The states $(U^\pm, V^\pm)$ lie on different branches of $S$, that is, $f^-(v) \neq f^+(v)$.

We will analyze traveling front solutions $(u, v)(\xi)$ satisfying $\lim_{\xi \to \pm \infty} (u, v)(\xi) = (U^\pm, V^\pm)$. The first condition (i) ensures that such a front is bistable, so that it forms an interface between asymptotically stable rest states; we will see that the resulting conditions (2.4) ensure hyperbolicity of relevant critical manifolds and the rest states in their associated reduced flows. We also remark that the condition on $G_v^\pm$ ensures the steady states remain stable for large advection $\nu \gg 1$ (see Appendix A); this prevents instabilities which can arise in the background states $(U^\pm, V^\pm)$ due to large differential flow [8, 45, 49], so that we focus only on instabilities which arise due to the interface itself.

The second condition (ii) ensures that the front interface is sharp; that is, in the appropriate slow-fast formulation (depending on the specific asymptotic regime of the parameters $\delta, \nu$), the front (in an appropriate singular limit) must traverse a singular fast heteroclinic orbit $u_*(\xi)$ of an associated layer problem in the subspace $v = v_*$ with leading order speed $c = c_*$, as opposed to being entirely contained within the reduced flow on a single connected...
branch of a slow manifold; for the latter situation, see e.g. [19]. The solution \( u_\ast(\xi) \) solves the simpler scalar traveling wave equation

\[
0 = u_{\xi\xi} + c_u u_\xi + F(u, v_\ast),
\]

and forms a fast connection between the branches of \( \mathcal{S} \), that is, \( u_\ast^\pm := \lim_{\xi \to \pm \infty} u_\ast(\xi) \) satisfy \( u_\ast^\pm = f^\pm(v_\ast) \). The existence of such a heteroclinic orbit in (2.5) can for instance be obtained in a given system using phase plane techniques. The fronts under consideration here traverse only one such fast heteroclinic orbit, i.e. they do not jump back and forth between several branches of \( \mathcal{S} \).

Beyond the conditions (i)-(ii) on the steady states \((U^\pm, V^\pm)\), additional structure is required concerning the reduced flows of certain critical manifolds which appear in the existence problem to allow for bistable traveling front solutions between several branches of \( \mathcal{S} \). However, since these conditions are related to the specific slow-fast formulation in each parameter regime, we delay their discussion until introducing the slow-fast structure of the fronts; see Assumptions 4 and 5 in §3 and §4, respectively. In the following section, we focus on the stability criterion which arises given a traveling wave solution which connects the steady states \((U^\pm, V^\pm)\).

### 2.2 Long-wave (in)stability of planar interfaces

Given a traveling wave solution \( \phi_h(\xi; r, \delta) = (u_h, v_h)(\xi; \nu, \delta) \) of (2.1) with speed \( c = c(\nu, \delta) \) satisfying \( \lim_{\xi \to \pm \infty} \phi_h(\xi; \nu, \delta) = (U^\pm, V^\pm) \), we linearize (2.1) using the ansatz \((U, V)(\xi, y, t) = (u_h, v_h)(\xi; \nu, \delta) + (u, v)(\xi)e^{\lambda t + iy} \), which results in the corresponding linear stability problem

\[
\begin{align*}
\lambda u &= u_{\xi\xi} + c_u u_\xi - \ell^2 u + F_u(u_h(\xi), v_h(\xi))u + F_v(u_h(\xi), v_h(\xi))v \\
\lambda v &= \frac{1}{\delta^2} v_{\xi\xi} + (\nu + c) v_\xi - \frac{\ell^2}{\delta^2} v + G_u(u_h(\xi), v_h(\xi))u + G_v(u_h(\xi), v_h(\xi))v,
\end{align*}
\]

(2.6)

parameterized by the transverse Fourier wavenumber \( \ell \in \mathbb{R} \). This can equivalently be written as the eigenvalue problem

\[
\mathcal{L} \begin{pmatrix}
u \\
\end{pmatrix} = \lambda \begin{pmatrix}
\begin{pmatrix}
u \\
\end{pmatrix}
\end{pmatrix} + \ell^2 \begin{pmatrix}
u \\
\end{pmatrix},
\]

(2.7)

where

\[
\mathcal{L} = \begin{pmatrix}
\partial_{\xi\xi} + c\partial_\xi + F_u(u_h(\xi), v_h(\xi)) & F_v(u_h(\xi), v_h(\xi)) \\
G_u(u_h(\xi), v_h(\xi)) & \frac{1}{\delta^2}\partial_{\xi\xi} + (\nu + c) \partial_\xi + G_v(u_h(\xi), v_h(\xi))
\end{pmatrix}.
\]

(2.8)

When \( \ell = 0 \), this eigenvalue problem is solved by taking \( \lambda = 0 \) and \((u, v) = (u^h, v^h)\) (due to translation invariance of the traveling wave ODE (2.2)). We make the following assumption regarding the stability of the front as a traveling wave in one space dimension, i.e. in the direction of propagation.

**Assumption 2.** (1D stability of the front) The operator \( \mathcal{L} \) satisfies \( \text{spec}\{\mathcal{L}\} \subset \{\lambda \in \mathbb{C} : \text{Re}\lambda < 0\} \cup \{0\} \). Furthermore, the eigenvalue \( \lambda = 0 \) is isolated and algebraically simple, and \( \mathcal{L} \) has one-dimensional generalized kernel spanned by the eigenfunction \((u^h, v^h)\).

In a given system, this assumption regarding 1D stability may be nontrivial to verify, and typically involves detailed estimates on the solution \((u_h, v_h)(\xi; \nu, \delta)\) and careful analysis of the equation (2.6) for \( \ell = 0 \) and \( \lambda \) in various regions of the complex plane. As this study is focused specifically on instabilities arising from the resulting two-dimensional interface, we do not pursue a detailed analysis of 1D stability here, but we note that this assumption can be verified for traveling fronts in specific systems using techniques of geometric singular perturbation theory, Lin’s method, and/or Evans function approaches [5, 20, 43].
To study the stability of the front to long wavelength perturbations in two spatial dimensions, we examine how this eigenvalue problem perturbs for values of $|\ell| \ll 1$. Following the (formal) analysis of [14] for the stability problem (2.6), we expand the critical translation eigenvalue $\lambda_c(\ell)$ satisfying $\lambda_c(0) = 0$ and the corresponding eigenfunction $(u_c, v_c)(\xi; \ell)$ as

$$
\lambda_c(\ell) = \lambda_{c,2}\ell^2 + O(\ell^4),
$$

where

$$
\begin{pmatrix}
  u_c(\xi; \ell) \\
  v_c(\xi; \ell)
\end{pmatrix} = \begin{pmatrix}
  u'_c(\xi) \\
  v'_c(\xi)
\end{pmatrix} + \ell^2 \begin{pmatrix}
  u_{c,2}(\xi) \\
  v_{c,2}(\xi)
\end{pmatrix} + O(\ell^4)
$$

(2.9)

Substituting into (2.7), at $O(\ell^2)$, we have the equation

$$
\mathcal{L} \begin{pmatrix}
  u_{c,2} \\
  v_{c,2}
\end{pmatrix} = \lambda_{c,2} \begin{pmatrix}
  u_h \\
  v_h
\end{pmatrix} + \begin{pmatrix}
  u'_h \\
  v'_h
\end{pmatrix}.
$$

(2.10)

In order for this equation to admit a solution, the inhomogeneous term on the right hand side must satisfy a Fredholm solvability condition [34]

$$
\left\langle \lambda_{c,2} \begin{pmatrix}
  u'_h \\
  v'_h
\end{pmatrix} + \begin{pmatrix}
  u'_h \\
  v'_h
\end{pmatrix}, \begin{pmatrix}
  u'\xi \\
  v'\xi
\end{pmatrix} \right\rangle = 0
$$

(2.11)

where $(u^A, v^A)(\xi)$ is the unique (up to scalar multiple) integrable eigenfunction of the corresponding adjoint equation

$$
\mathcal{L}^A \begin{pmatrix}
  u \\
  v
\end{pmatrix} = 0,
$$

(2.12)

where the adjoint operator $\mathcal{L}^A$ is given by

$$
\mathcal{L}^A = \begin{pmatrix}
  \partial_{\xi\xi} - c\partial_{\xi} + F_u(u_h(\xi), v_h(\xi)) \\
  F_v(u_h(\xi), v_h(\xi))
\end{pmatrix} \begin{pmatrix}
  G_u(u_h(\xi), v_h(\xi)) \\
  1/\ell^2 \partial_{\xi\xi} - (\nu + c) \partial_{\xi} + G_v(u_h(\xi), v_h(\xi))
\end{pmatrix}.
$$

(2.13)

Equivalently, solving (2.11) for $\lambda_{c,2}$, we obtain

$$
\lambda_{c,2} = -\frac{\int_{-\infty}^{\infty}(u'_h(\xi)u^A(\xi) + \frac{1}{\ell^2}v'_h(\xi)v^A(\xi)) \, d\xi}{\int_{-\infty}^{\infty}(u'_h(\xi)u^A(\xi) + v'_h(\xi)v^A(\xi)) \, d\xi}.
$$

(2.14)

The sign of $\lambda_{c,2}$ determines the 2D stability of the front $(u_h, v_h)$ to perturbations with small transverse wavenumber $|\ell| \ll 1$. As with the slow-fast structure of the fronts themselves, the structure of the stability problem (2.6) and the computation of the adjoint solution $(u^A, v^A)(\xi)$ change depending on the relative size(s) of the parameters $\nu, \delta$. Hence we must split the computation of $\lambda_{c,2}$ into cases corresponding to different scaling regimes as described in §2.1.

### 2.3 Summary of results

By considering the slow-fast construction of traveling fronts in the weak advection, intermediate, and strong advection regimes, we determine leading order asymptotics for the critical coefficient $\lambda_{c,2}$ (2.14) which determines long wavelength instabilities along the front interface. We will see that the sign of this coefficient depends only on information encoded in the fast layer orbit $u_*(\xi)$ of (2.5) in the subspace $v = v_*$ in the singular slow-fast framework. We impose one additional nondegeneracy assumption

**Assumption 3.** (Nondegeneracy condition) The quantity $G(u^+_*, v_*) - G(u^-*_, v_*) \neq 0$.

Under Assumptions 1–3, for a traveling front $\phi_h$ which traverses a single fast jump $u_*(\xi)$ of the reduced equation (2.5), we obtain an asymptotic long-wavelength stability criterion which holds throughout the weak advection, strong advection, and intermediate regimes. To summarize, letting $r_0$ and $R_0$ denote sufficiently small and sufficiently large fixed positive constants, respectively, for sufficiently small $\delta_0 > 0$ we find the following asymptotic stability criteria by determining the sign of $\lambda_{c,2}$ for $0 < \delta \ll \delta_0 \ll 1$:
• **Weak advection regime:** $0 \leq \nu \leq \frac{R_0}{\delta}$. In this regime, to leading order
\[
sign(\lambda_{c,2}) = -\text{sign}(F_*) \times \text{sign}(G_*)
\]
where
\[
F_* := \int_{-\infty}^{\infty} F_0(u_*(\xi), v_*) e^{\xi - \xi^2_0} u_*(\xi) \, d\xi,
\]
and $u_*(\xi) := \lim_{\xi \to \pm \infty} u_*(\xi)$.  

• **Intermediate regime:** $\frac{R_0}{\delta} \leq \nu \leq \frac{r_0}{\delta^2}$. In this regime, to leading order
\[
sign(\lambda_{c,2}) = \text{sign} \left( -1 + \frac{M}{\delta^4 \nu^3} \right)
\]
where $M = \mathcal{O}(1)$ with respect to $\delta, \nu$, and $\text{sign}(M) = -\text{sign}(F_*) \times \text{sign}(G_*)$. In particular, if $M > 0$, then to leading order, $\lambda_{c,2}$ changes sign when $\nu \sim M^{1/3} \delta^{-4/3}$.

• **Strong advection regime:** $\nu \geq \frac{r_0}{\delta^2}$. Throughout this regime, to leading order we find that
\[
sign(\lambda_{c,2}) = -1.
\]

The asymptotic estimates are uniform in sufficiently small $\delta$, so that the three regimes collectively describe the parameter region $\{(\delta, \nu) : 0 < \delta \leq \delta_0, 0 \leq \nu < \infty\}$ for some suitably small choice of $\delta_0 > 0$. In the weak advection regime, the stability of traveling fronts to long wavelength perturbations is encoded purely in the nonlinearities $F$ and $G$, evaluated along the fast heteroclinic orbit $u_*(\xi)$. This criterion is analogous to that obtained in [14] in the absence of advection, and in the limit $\nu \to 0$ the corresponding expression for $\lambda_{c,2}$ agrees with that found in [14, §2]. As $\nu$ increases relative to $\delta$, in the intermediate regime, depending on the nonlinearities $F$ and $G$ and the relative size of $\nu$ with respect to $\delta$, traveling fronts can be stable or unstable to long wavelength perturbations, with a potential sign change of $\lambda_{c,2}$ occurring at the critical scaling $\nu \sim \mathcal{O}(\delta^{-4/3})$. Finally, in the strong advection regime, all bistable traveling fronts considered here are stable to long wavelength perturbations. In this sense, the presence of advection has a stabilizing effect on the front as a planar interface.

To obtain the stability criteria above, we employ a mixture of geometric singular perturbation theory and formal asymptotic arguments to construct the adjoint solution $(u^A, v^A)(\xi)$ and estimate the expression (2.14) in each of the scaling regimes. However, we emphasize that the results above could in principle be obtained rigorously using geometric singular perturbation methods, in combination with exponential dichotomies/trichotomies and Lin’s method, or Evans function approaches; see e.g. [5, 47] for thorough analyses of stability of planar traveling fronts and stripe solutions in specific reaction-diffusion-advection equations. However, for our purposes, we believe that such a technical analysis would detract from the simple message herein, that the presence of advection has a stabilizing effect on planar interfaces, and a straightforward stability criterion which can easily be applied in many example systems.

The remainder of the paper is outlined as follows. In §3 we describe the construction of traveling fronts and the leading order computation of $\lambda_{c,2}$ in the weak advection and intermediate regimes, while the strong advection regime is considered in §4. In §5, we apply these results to an explicit dryland ecosystem model, and §6 contains some numerical simulations and a brief discussion of the results.

## 3 Weak advection and intermediate regimes

Due to the similarity in the slow-fast geometry associated with the weak advection and intermediate regimes, in this section we consider both regimes, and outline the differences in each case. Taken together, we consider the regime
0 \leq \nu \leq \frac{\delta_0}{\delta}, or equivalently 0 \leq r \leq r_0, where r_0 is a (yet to be fixed) small parameter. Therefore, we are interested in the behavior of the traveling wave equation (2.2) when both \delta and r = \delta^2 \nu can be taken as small parameters.

This leads to a system with (up to) three timescales, and there is a distinction between the singular limits obtained by taking \delta \to 0 with r fixed, versus r \to 0 with \delta fixed. Hence the case 0 \leq r \leq r_0 needs to be split into two subcases: (i) \( r = \bar{r} \delta, \bar{r} \leq \bar{R}_0 \), corresponding to the weak advection regime and (ii) \( \delta = \bar{\delta} r, \bar{\delta} \leq \delta_0 \), corresponding to the intermediate regime. We begin by describing the slow-fast structure of traveling fronts in each case in §3.1, followed by a computation of the coefficient \( \lambda_{c,2} \) in §3.2.

### 3.1 Structure of traveling fronts

The structure of the orbits in each case is similar, but with a different parameter used as the timescale separation parameter (\( \delta \) vs. \( r \)) in each case. We consider the first case in detail, and then outline differences relevant for the analysis of the second case.

#### 3.1.1 Case (\( \bar{r} \)) : \( r = \bar{r} \delta, 0 \leq \bar{r} \leq \bar{R}_0 \)

We set \( r = \bar{r} \delta \) in (2.3), obtaining

\[
\begin{align*}
\delta u_\xi &= p \\
\delta p_\xi &= -cp - F(u,v) \\
\delta v_\xi &= \delta q \\
\delta q_\xi &= -\delta ((\bar{r} + \delta c)q + G(u,v)).
\end{align*}
\]

which we aim to analyze for all \( 0 \leq \bar{r} \leq \bar{R}_0 \) for fixed \( \bar{R}_0 > 0 \), where \( \bar{R}_0 \) is a large constant which is \( \mathcal{O}(1) \) with respect to \( \delta \). This results in a 2-fast-2-slow system with timescale separation parameter \( \delta \). Setting \( \delta = 0 \), we obtain the layer problem

\[
\begin{align*}
\delta u_\xi &= p \\
\delta p_\xi &= -cp - F(u,v).
\end{align*}
\]

We recall, by Assumption 1, that the set \( S = \{ F(u,v) = 0 \} \) has two (different) branches \( S^\pm \) given by graphs \( u = f^\pm(v) \) for \( v \in I^\pm_v \), where \( f^\pm(V^\pm) = U^\pm \). As the branches are defined away from points where \( F_u = 0 \), by Assumption 1(i) , the quantity \( F_u \) has fixed (negative) sign on the branches \( S^\pm \). Therefore, the layer problem (3.2) admits two hyperbolic equilibria given by \( u = f^\pm(v), p = 0 \) for \( v \in I^\pm_v \), respectively, so that (3.1) admits a two-dimensional critical manifold \( M_0 := \{ p = 0, F(u,v) = 0 \} \), consisting of (at least) two branches

\[
M_0^- = \{ p = 0, u = f^-(v), v \in I^+_v \}, \quad M_0^+ = \{ p = 0, u = f^+(v), v \in I^+_v \},
\]

where \( F(f^\pm(v), v) = 0 \), and \( V^- \in I^-_v, V^+ \in I^+_v \). Assumption 1(i) implies that \( M_0^\pm \) are of saddle type in their respective regions of definition. Using phase plane techniques, by appropriately adjusting the wave speed \( c \), if \( I^-_v \cap I^+_v \neq \emptyset \), then for any \( v, v \in I^-_v \cap I^+_v \), there exists a locally unique speed \( c_v \) and corresponding heteroclinic orbit \( u_v(\xi) \) between the saddle branches \( M_0^- \) and \( M_0^+ \) lying in the intersection \( \mathcal{W}^u(M_0^-) \cap \mathcal{W}^s(M_0^+) \); see Figure 3.

We now rescale \( \zeta = \delta \xi \) and consider the corresponding slow system

\[
\begin{align*}
\delta u_\zeta &= p \\
\delta p_\zeta &= -cp - F(u,v) \\
\delta v_\zeta &= q \\
\delta q_\zeta &= -((\bar{r} + \delta c)q + G(u,v)).
\end{align*}
\]

8
Figure 3 – Shown is a schematic of the slow-fast construction of the singular traveling front in the weak advection regime. (Left) The fast jump \( u_*(\xi) \) of the layer problem (3.2) between the manifolds \( \mathcal{M}_0^\pm \) in \((u, v, q)\)-space. (Right) Intersection of (projection of) manifolds \( L_u^- \) and \( L_s^+ \) of the reduced flows (3.6) as in Assumption 4.

Setting \( \delta = 0 \), we obtain the corresponding reduced system

\[
0 = p \\
0 = -cp - F(u, v) \\
v_\zeta = q \\
q_\zeta = -(\bar{r}q + G(u, v)).
\]

(3.5)

in which the flow is restricted to the critical manifold \( \mathcal{M}_0 \). The reduced flow on each of the saddle branches \( \mathcal{M}_0^- \) and \( \mathcal{M}_0^+ \) is given by the planar flows

\[
v_\zeta = q \\
q_\zeta = -(\bar{r}q + G(f^\pm(v), v)).
\]

(3.6)

or equivalently the scalar equations

\[
v_\zeta + \bar{r}_v q + G(f^\pm(v), v) = 0
\]

(3.7)

By Assumption 1(i), \((U^+, V^+) = (f^+(V^+), V^+)\) are fixed points of the full system. Since

\[
(f^\pm)'(v) = -F_v(f^\pm(v), v)/F_u(f^\pm(v), v),
\]

the conditions (2.4) imply that \( G_u(f^\pm(V^\pm), V^\pm)(f^\pm)'(V^\pm) + G_v(f^\pm(V^\pm), V^\pm) < 0 \), and hence \((v, q) = (V^\pm, 0)\) correspond to saddle fixed points of the reduced flows (3.6) on \( \mathcal{M}_0^\pm \), respectively. We denote by \( L^{s,u}_\pm \) the stable/unstable manifolds of the fixed points \((V^\pm, 0)\). In this setting, to ensure the existence of a traveling front for \( 0 < \delta \ll 1 \), we need to make the following assumption, which can be checked in a given system by examining the planar flows (3.6) for given \( \bar{r} \) and nonlinearity \( G(u, v) \) (see right panel of Figure 3).

Assumption 4. The projection of the manifold \( L_u^- \) from \( \mathcal{M}_0^- \) onto \( \mathcal{M}_0^+ \) transversely intersects \( L_s^+ \) at \((v, q) = (v_*, q_*)\) for some \( v_* \in I_v^- \cap I_v^+ \).

Considering the manifolds \( L^{s,u}_\pm \) as subsets of the critical manifold \( \mathcal{M}_0 \) and taking the union of their fast (un)stable fibers, we can construct the singular two-dimensional stable and unstable manifolds of the equilibria \( P^\pm \) in the full system as \( W^{s,u}(P^\pm) := W^{s,u}(L^{s,u}_\pm) \subset W^{s,u}(\mathcal{M}_0^\pm) \).
A singular heteroclinic orbit between the equilibria $P^\pm$ can then be formed by concatenating slow-fast trajectories from the layer/reduced problems as follows. The solution leaves $P^-$ along the slow unstable manifold $L^u_\pm \subset \mathcal{M}_0^\pm$, then departs $\mathcal{M}_0^\pm$, along a fast jump contained within $\mathcal{W}^u(L^u_\pm)$ at the critical jump value $v = v_*$. Combining the analysis of the layer problem (3.2) above with Assumption 4, by choosing $c = c_*$ appropriately this fast jump forms a heteroclinic orbit which lies in the intersection $\mathcal{W}^u(L^u_\pm) \cap \mathcal{W}^s(L^s_\pm)$. The orbit then tracks $L^s_\pm$ until reaching $P^+$; see Figure 3. This sequence forms a singular orbit from which, for sufficiently small $\delta_0 > 0$, a solution to the full system (2.3) for $0 < \delta \leq \delta_0$ with speed $c = c_* + \mathcal{O}(\delta)$ can be obtained using geometric singular perturbation theory.

3.1.2 Case (ii): $\delta = \tilde{\delta}r, 0 < \tilde{\delta} \leq \delta_0$

We now consider $r \ll 1$ and set $\delta = \tilde{\delta}r$ in (2.3), obtaining

\begin{align}(3.8)\begin{align} u_\xi &= p \\
 p_\xi &= -cp - F(u, v) \\
 q_\xi &= \bar{r}q \\
 \bar{q}_\xi &= -r \left((1 + \bar{\delta}^2 r\bar{c})q + \bar{\delta}G(u, v)\right).
\end{align}\end{align}

which we similarly aim to analyze for all $0 < \bar{\delta} < \delta_0$ for any $\bar{\delta}_0 > 0$ where $\bar{\delta}_0$ is a small constant which is $\mathcal{O}(1)$ with respect to $r$. This system is now a 2-fast-2-slow system with timescale separation parameter $r$, and $\bar{\delta}$ as an additional small parameter. For $\delta$ bounded away from zero, the analysis proceeds similarly as in the previous section. However, for sufficiently small $\bar{\delta}$, in order to obtain the precise form of the expression (2.17), we require more detailed estimates on the existence problem.

First, we rescale $q = \bar{\delta}\bar{q}$, to obtain the system

\begin{align}(3.9)\begin{align} u_\xi &= p \\
 p_\xi &= -cp - F(u, v) \\
 q_\xi &= \delta^2 \bar{q} \\
 \bar{q}_\xi &= -\bar{q} - G(f^\pm(v), v).
\end{align}\end{align}

Setting $\tau = r\xi$, we obtain the reduced flow for $r = 0$ on the manifolds $\mathcal{M}_0^\pm$

\begin{align}(3.10)\begin{align} v_\tau &= \delta^2 \bar{q} \\
 \bar{q}_\tau &= -\bar{q} - G(f^\pm(v), v),
\end{align}\end{align}

which can be analyzed as planar slow-fast system with singular perturbation parameter $\delta^2$. In particular, this allows us to easily determine the manifolds $L^u_\pm$ and $L^s_\pm$. Note that in the limit $\delta \to 0$, there exist normally attracting invariant manifolds $\mathcal{C}_0^\pm = \{ \bar{q} = -G(f^\pm(v), v) \} \subset \mathcal{M}_0^\pm$ with corresponding reduced flows

\begin{align}(3.11)\begin{align} v_\tau &= -G(f^\pm(v), v)
\end{align}\end{align}

where $\bar{\tau} = \delta^2 \tau$. As argued in §3.1.1, Assumption 1 implies that the quantities $\kappa_\pm := G_u(f^\pm(V^\pm), V^\pm)(f^\pm)'(V^\pm) + G_v(f^\pm(V^\pm), V^\pm) < 0$, and hence the fixed points $v = V^\pm$ are repelling within $\mathcal{C}_0^\pm$. Since the manifolds $\mathcal{C}_0^\pm$ are normally attracting in the reduced flow (3.10), they perturb to locally invariant manifolds $\mathcal{C}_0^\pm$ for all sufficiently small $\delta$, we deduce that the manifold $L^u_\pm$ corresponds to the perturbed manifold $\mathcal{C}_0^\pm$ given as a graph $\bar{q} = -G(f^\pm(v), v) + \mathcal{O}(\delta^2)$, and $L^s_\pm$ corresponds to the perturbed stable fiber of $\mathcal{C}_0^\pm$ which meets $\mathcal{C}_0^\pm$ at $v = V^\pm$, and can be written as a graph $v = V^\pm + \mathcal{O}(\delta^2)$. For the manifolds $L^u_\pm$ and $L^u_\pm$ to intersect in their combined projection, as in Assumption 4, for all small $\tilde{\delta} > 0$, they do so at a point $v_\pm = V^\pm + \mathcal{O}(\delta^2)$ and $\bar{q}_\pm = \mathcal{O}(\delta^2)$, which therefore defines the critical jump value and corresponding speed $c = c_*$ in the fast subsystem. Denoting by $v^\pm(\tau)$ the solutions corresponding to $L^\pm_\pm$.
and $L^w_-$ satisfying $v^w(0) = v_*$, we have that
\begin{align}
v^w_-(\tau) &= -\delta^2 G(f^-(v^-)(\tau)), v^-(\tau)) + O(\delta^4), \quad \tau < 0 \\
v^w_+(\tau) &= O(\delta^4), \quad \tau > 0, \tag{3.12}
\end{align}
and $v^w_+ (\tau)$ decays with exponential rate $-1 + \delta^2 \kappa_+$ to leading order as $\tau \to \infty$.

**Remark 3.1.** Assuming $V^- > V^+$, without loss of generality, we note that to ensure that Assumption 4 holds for all sufficiently small $\delta$, it suffices to assume that $G(f^-(v), v) < 0$ for all $v \in [V^+, V^-)$. This connects the structure of the existence problem in the intermediate regime to that in the strong advection regime; see §4.1 and Assumption 5.

Using this construction in the region of small $\delta$, we therefore obtain singular heteroclinic orbits for all $0 < \delta < \delta_0$, which can be shown, using geometric singular perturbation techniques, to perturb to traveling front solutions with speed $c = c_* + O(r)$ for all $0 < r < r_0$ for some $r_0 \ll 1$. Fixing $\delta_0$ sufficiently small above, and taking $R_0 > \delta_0^{-1}$ in §3.1.1, and possibly taking $r_0$ and/or $\delta_0$ smaller if necessary, we can combine these results with those of the previous section to obtain a slow-fast description of singular traveling fronts for any $0 \leq r \leq r_0$, $0 < \delta \leq \delta_0$. The boundary between the weak and intermediate regimes occurs when $r = O(\delta)$, or equivalently when $\nu = O(\delta^{-1})$.

### 3.2 Long wavelength (in)stability: leading order computation of $\lambda_{c,2}$

Given the slightly different slow-fast structures of the weak advection and intermediate regimes in §3.1, we similarly separate the computation of $\lambda_{c,2}$ in each case, depending on whether $\delta$ or $r$ is used as the primary singular perturbation parameter. In each case, the goal is to approximate (2.14) by obtaining leading order expressions for the adjoint solution $(u^A, v^A)(\xi)$ in the corresponding fast and slow fields.

#### 3.2.1 Case (i): $r = \bar{r}\delta, 0 \leq \bar{r} \leq R_0$

We consider the fast
\begin{align}
u_{\xi\xi} - cu_{\xi} + F_u(u_h(\xi), v_h(\xi))u + G_u(u_h(\xi), v_h(\xi))v &= 0 \\
v_{\xi\xi} - (\bar{r}\delta + \delta^2 c) v_{\xi} + \delta^2 F_v(u_h(\xi), v_h(\xi))u + \delta^2 G_v(u_h(\xi), v_h(\xi))v &= 0 \tag{3.13}
\end{align}
and slow
\begin{align}
\delta^2 u_{\zeta\zeta} - cu_{\zeta} + F_u(u_h(\zeta/\delta), v_h(\zeta/\delta))u + G_u(u_h(\zeta/\delta), v_h(\zeta/\delta))v &= 0 \\
v_{\zeta\zeta} - (\bar{r} + \delta c) v_{\zeta} + F_v(u_h(\zeta/\delta), v_h(\zeta/\delta))u + G_v(u_h(\zeta/\delta), v_h(\zeta/\delta))v &= 0 \tag{3.14}
\end{align}
formulations of the adjoint equation (2.12). In the fast field, to leading order $u_h(\xi) = u_*(\xi), v_h(\xi) = v_*$, and $c = c_*$, so that to leading order the fast system is given by
\begin{align}
u_{\xi\xi} - c_* u_{\xi} + F_u(u_*(\xi), v_*)u + G_u(u_*(\xi), v_*)v &= 0 \\
v_{\xi\xi} &= 0 \tag{3.15}
\end{align}
from which we deduce that $v = \bar{v}_* = \text{constant}$ and $u$ satisfies
\begin{equation}
u_{\xi\xi} - c_* u_{\xi} + F_u(u_*(\xi), v_*)u = -G_u(u_*(\xi), v_*)\bar{v}_*. \tag{3.16}
\end{equation}
The left hand side of (3.16) can be written as $L^A_+ u$, where
\begin{equation}
L^A_+ := \partial_{\xi\xi} - c_* \partial_{\xi} + F_u(u_*(\xi), v_*) \tag{3.17}
\end{equation}
is the adjoint of the linearization
\begin{equation}
L_* := \partial_{\xi\xi} + c_* \partial_{\xi} + F_u(u_*(\xi), v_*) \tag{3.18}
\end{equation}
of the reduced system (2.5) along the fast jump. The kernel of $L_\omega$ is spanned by the derivative $u'_\omega(\xi)$ of the fast heteroclinic orbit $u_\omega(\xi)$, while $u'_\omega(\xi)e^{c_\omega\xi}$ is the bounded solution of the adjoint equation $L^*_\omega u = 0$. Taking the inner product of (3.16) with $u'_\omega(\xi)$ implies that

$$0 = \bar{v}_\omega \int_{-\infty}^{\infty} G_\omega(u_\omega(\xi), v_\omega) u'_\omega(\xi) d\xi = \bar{v}_\omega \left( G(u^+_\omega, v_\omega) - G(u^-_\omega, v_\omega) \right),$$

(3.19)

By Assumption 3, $G(u^+_\omega, v_\omega) \neq G(u^-_\omega, v_\omega)$ so that $\bar{v}_\omega = 0$, and to leading order $v = 0$ and $u = \alpha_\omega u'_\omega(\xi)e^{c_\omega\xi}$.

For the slow system, we denote by $v^\pm(\zeta)$ the slow orbits of (3.6) corresponding to $L^u_\omega$ and $L^s_\omega$, respectively, which satisfy $v^\pm(0) = v_\omega$. At leading order we find that

$$F_u(f^\pm(v^\pm), v^\pm) + G_u(f^\pm(v^\pm), v^\pm) v = 0$$

$$v_{\zeta\zeta} - \bar{r} v_\zeta + F_v(f^\pm(v^\pm), v^\pm) + G_v(f^\pm(v^\pm), v^\pm) v = 0,$$

(3.20)

or equivalently

$$v_{\zeta\zeta} - \bar{r} v_\zeta + \left( G_v(f^\pm(v^\pm), v^\pm) - F_v(f^\pm(v^\pm), v^\pm) \frac{G_u(f^\pm(v^\pm), v^\pm)}{F_u(f^\pm(v^\pm), v^\pm)} \right) v = 0,$$

(3.21)

from which we deduce that $v^{A,\pm}(\zeta) = \delta \alpha_\omega e^{c_\omega \zeta} v^{\pm}_\zeta(\zeta)$. To match along the fast jump, we note that to ensure continuity of $v^{A,\pm}$, we require $\alpha_\omega^+ = \alpha_\omega^- = \alpha$ since $v^{\pm}_\zeta(0) = q_\omega = v^{\pm}_\zeta(0)$. There is an offset in $v^{A,\pm}_\zeta$ from the slow equations across the fast jump since by (3.7) we have

$$\left[ (e^{c_\omega v^{\pm}_\zeta(\zeta)})_{\zeta} - (e^{c_\omega v^{\pm}_\zeta(\zeta)})_{\zeta} \right]_{\zeta=0} = v^{A,\pm}_\zeta(0) - v^{A,-}_\zeta(0) = - \left( G(u^+_\omega, v_\omega) - G(v^-_\omega, v_\omega) \right),$$

(3.22)

so that

$$v^{A,\pm}_\zeta(0) - v^{A,-}_\zeta(0) = \delta \left( v^{A,\pm}_\zeta(0) - v^{A,-}_\zeta(0) \right) = \delta^2 \alpha \left( v^{A,\pm}_\zeta(0) - v^{A,-}_\zeta(0) \right) = - \delta^2 \alpha \left( G(u^+_\omega, v_\omega) - G(v^-_\omega, v_\omega) \right).$$

(3.23)

We therefore require a corresponding jump through the fast field. Integrating (3.13) over the fast field, and recalling that to leading order $v = \bar{v}_\omega = 0$ and $u = \alpha_\omega u'_\omega(\xi)e^{c_\omega\xi}$, we have to leading order

$$\Delta v^{A,\pm}_\zeta = \delta^2 \bar{F} \left( v^{A,\pm}_\zeta(0) - v^{A,-}_\zeta(0) \right) - \delta^2 \alpha_\omega \int_{-\infty}^{\infty} F_v(u_\omega(\xi), v_\omega)e^{c_\omega\xi} u'_\omega(\xi) d\xi = - \delta^2 \alpha_\omega \int_{-\infty}^{\infty} F_v(u_\omega(\xi), v_\omega)e^{c_\omega\xi} u'_\omega(\xi) d\xi,$$

(3.24)

which, upon equating (3.23) and (3.24), we deduce that

$$\alpha = \alpha_\omega \frac{\int_{-\infty}^{\infty} F_v(u_\omega(\xi), v_\omega)e^{c_\omega\xi} u'_\omega(\xi) d\xi}{G(u^+_\omega, v_\omega) - G(v^-_\omega, v_\omega)}.$$

(3.25)

We now compute

$$\int_{-\infty}^{\infty} u'_\omega(\xi) v^A(\xi) d\xi = \int_{-\infty}^{\frac{\sqrt{3}}{2}} u'_\omega(\xi) v^A(\xi) d\xi + \int_{\frac{\sqrt{3}}{2}}^{\frac{\sqrt{3}}{2}} u'_\omega(\xi) v^A(\xi) d\xi + \int_{\frac{\sqrt{3}}{2}}^{\infty} u'_\omega(\xi) v^A(\xi) d\xi$$

$$= \alpha \int_{-\frac{\sqrt{3}}{2}}^{\frac{\sqrt{3}}{2}} \delta e^{c_\omega v^-_\zeta(\xi)} d\xi + \alpha \int_{-\frac{\sqrt{3}}{2}}^{\frac{\sqrt{3}}{2}} \delta^2 \bar{F} d\xi + \alpha \int_{\frac{\sqrt{3}}{2}}^{\infty} \delta e^{c_\omega v^+_\zeta(\xi)} d\xi + O(\alpha \delta^2)$$

$$= \alpha \int_{-\frac{\sqrt{3}}{2}}^{\frac{\sqrt{3}}{2}} \delta e^{c_\omega v^-_\zeta(\xi)} d\xi + \alpha \int_{\frac{\sqrt{3}}{2}}^{\infty} \delta e^{c_\omega v^+_\zeta(\xi)} d\xi + O(\alpha \delta^3/2)$$

and similarly

$$\int_{-\infty}^{\infty} u'_\omega(\xi) u^A(\xi) d\xi = \alpha \left( \int_{-\infty}^{\infty} e^{c_\omega\xi} u'_\omega(\xi) d\xi + O(\delta) \right)$$

12
so that to leading order, we estimate (2.14) as

$$\lambda_{c,2} \sim \frac{1}{\delta} \int_{-\infty}^{\infty} \frac{F_v(u_*(\xi), v_*) e^{c_\xi \xi} u'_*(\xi) d\xi}{G(u_*, v_*) - G(u_*, v_*)} \left( \int_{-\infty}^{0} e^{c_\xi \xi} v^{-}_*(\xi) d\xi + \int_{0}^{\infty} e^{c_\xi \xi} v^+_*(\xi) d\xi \right).$$

(3.26)

The last factor has fixed sign so that we immediately obtain the stability criterion (2.15) in the weak advection regime in terms of the quantities (2.16). The leading order asymptotic formula (3.26) holds provided \( \nu = \tilde{\nu}, 0 \leq \tilde{\nu} \leq \bar{R}_0, 0 < \delta \leq \bar{\delta}, \) or in terms of \( \nu, \) provided \( 0 \leq \nu \leq \frac{R_0}{e}. \) We note that the case \( \nu = 0 \) corresponds to setting \( \tilde{\nu} = 0 \) in (3.26), which matches the expression obtained for the coefficient \( \lambda_{c,2} \) in the absence of advection in [14, §2].

### 3.2.2 Case (ii): \( \delta = \tilde{\delta} r, 0 < \delta \leq \bar{\delta}_0 \)

We again consider the fast

$$u_{xx} - ca_x + F_v(u_*(\xi), v_*(\xi))u + G_v(u_*(\xi), v_*(\xi))v = 0$$

(3.27)

and slow

$$r^2 u_{\tau\tau} - r c u_\tau + F_v(u_*(\tau/r), v_*(\tau/r))u + G_v(u_*(\tau/r), v_*(\tau/r))v = 0$$

(3.28)

formulations of the adjoint equation. At leading order the fast system is given by

$$u_{xx} - c_* u_x + F_v(u_*(\xi), v_*)u + G_v(u_*(\xi), v_*)v = 0$$

(3.29)

$$v_{xx} = 0$$

from which we deduce as in §3.2.1 that to leading order \( v = 0 \) and \( u(\xi) = \alpha_* e^{c_* \xi} u'_*(\xi) \). For the slow system, recalling that \( v^\pm(\tau) \) denote the solutions of (3.10) corresponding to \( L^+_v \) and \( L^-_v \) satisfying \( v^\pm(0) = v_* \), at leading order we find that

$$F_v(f^\pm(v^\pm), v^\pm)u + G_v(f^\pm(v^\pm), v^\pm)v = 0$$

(3.30)

$$v_{\tau\tau} - v_\tau + \delta^2 F_v(f^\pm(v^\pm), v^\pm)u + \delta^2 G_v(f^\pm(v^\pm), v^\pm)v = 0$$

(3.31)

or equivalently

$$v_{\tau\tau} - v_\tau + \delta^2 \left( G_v(f^\pm(v^\pm), v^\pm) - F_v(f^\pm(v^\pm), v^\pm) \right) \frac{G_v(f^\pm(v^\pm), v^\pm)}{F_v(f^\pm(v^\pm), v^\pm)} v = 0,$$

(3.32)

from which we deduce that \( v^A(\tau) = r \alpha^A e^{\tau} v^\pm_\tau(\tau) \) in the slow fields. To match along the fast jump, we note that to ensure continuity of \( v^A \), we require \( \alpha^+ = \alpha^- = \alpha \) since \( v^+_\tau(0) = v^-_\tau(0) \). Proceeding as in §3.2.1, to account for the jump in \( v^A_\tau \) from the slow equations across the fast jump

$$[(e^{\tau} v^+_\tau(\tau) - e^{\tau} v^-_\tau(\tau))_{\tau=0} = v^+_\tau(0) - v^-_\tau(0) = -\delta^2 (G(u^+_*, v_*) - G(u^-_*, v_*)),$$

(3.33)

we require a corresponding jump through the fast field

$$\Delta v^A_\xi = -\delta^2 r^2 \alpha_* \int_{-\infty}^{\infty} F_v(u_*(\xi), v_*) e^{c_\xi \xi} u'_*(\xi) d\xi = r^2 \alpha (v^+_\tau(0) - v^-_\tau(0)),$$

(3.34)

which implies

$$\alpha = \alpha_* \frac{\int_{-\infty}^{\infty} F_v(u_*(\xi), v_*) e^{c_\xi \xi} u'_*(\xi) d\xi}{G(u^+_*, v_*) - G(u^-_*, v_*)}.$$
Using the estimates of §3.1.2, we similarly proceed as in §3.2.1 and estimate
\[
\int_{-\infty}^{\infty} v_{\xi}(\xi)v^A(\xi)d\xi = \int_{-\infty}^{1/\sqrt{\tau}} v_{\xi}(\xi)v^A(\xi)d\xi + \int_{1/\sqrt{\tau}}^{\infty} v_{\xi}(\xi)v^A(\xi)d\xi + \int_{-\infty}^{\infty} v_{\xi}(\xi)v^A(\xi)d\xi
\]
\[
= \alpha \int_{-\infty}^{1/\sqrt{\tau}} \tau^{-1/2} \tau^{2} d\tau \alpha \int_{1/\sqrt{\tau}}^{\infty} \tau^{-1/2} \tau^{2} d\tau + \mathcal{O}(\alpha \delta^4 r^{3/2})
\]
\[
= \alpha r \delta^4 \left( \int_{-\infty}^{\infty} e^\tau G(f^-(v^-)(\tau), v^-)(\tau)^2 d\tau + \mathcal{O}(\delta^2, \sqrt{\tau}) \right)
\]
\[
\int_{-\infty}^{\infty} u_{\xi}(\xi)u^A(\xi)d\xi = \alpha \left( \int_{-\infty}^{\infty} e^{-\xi} u_{\xi}(\xi)^2 d\xi + \mathcal{O}(r) \right),
\]
where we used the estimate (3.12) and the fact that $\delta \leq \delta_0$ is small. We now estimate (2.14) to leading order as
\[
\lambda_{c:2} \sim -1 - \frac{\alpha r \delta^4}{\alpha \delta^2} \left( \int_{-\infty}^{\infty} e^\tau G(f^-(v^-)(\tau), v^-)(\tau)^2 d\tau + \mathcal{O}(\delta^2, \sqrt{\tau}) \right)
\]
\[
= -1 - \frac{\delta^2}{r} \int_{-\infty}^{\infty} F_\tau(u_{\xi}(\xi), v_{\xi})e^{-\xi} u_{\xi}(\xi)d\xi \left( \int_{-\infty}^{\infty} e^\tau G(f^-(v^-)(\tau), v^-)(\tau)^2 d\tau \right) + \mathcal{O}(\delta^4) .
\]
From this, we obtain the stability criterion (2.17) in the intermediate regime. The leading order expression (2.17) is valid provided $\delta = \delta r, 0 < \delta \leq \delta_0, 0 \leq r \leq r_0$, or in terms of $\nu$, provided $\frac{1}{\delta \delta_0} \leq \nu \leq \frac{\nu_0}{\delta \delta_0}$; since $\delta_0 \geq 1$, this similarly holds for $\nu$ satisfying $\frac{R_0}{\delta \delta_0} \leq \nu \leq \frac{R_0}{\delta \delta_0}$. We see that the first (constant) term $-1$ dominates when $\delta^2 \ll r$, while the second term dominates when $r \ll \delta^2$. If the coefficient of the latter is positive, then the expression (3.35) changes sign when
\[
r = -\frac{\delta^2}{r} \int_{-\infty}^{\infty} F_\tau(u_{\xi}(\xi), v_{\xi})e^{-\xi} u_{\xi}(\xi)d\xi \left( \int_{-\infty}^{\infty} e^\tau G(f^-(v^-)(\tau), v^-)(\tau)^2 d\tau \right) + \mathcal{O}(\delta^4) ,
\]
or equivalently when
\[
\nu = M^{1/3} \delta^{-4/3} \left( 1 + \mathcal{O}(\delta^{2/3}) \right)
\]
where
\[
M := -\frac{\delta^2}{r} \int_{-\infty}^{\infty} F_\tau(u_{\xi}(\xi), v_{\xi})e^{-\xi} u_{\xi}(\xi)d\xi \left( \int_{-\infty}^{\infty} e^\tau G(f^-(v^-)(\tau), v^-)(\tau)^2 d\tau \right) + \mathcal{O}(\delta^4) .
\]
We emphasize that the sign of $M$ is determined by the same quantities $F_\tau, G_\tau$ defined in (2.16) which determine the sign of $\lambda_{c:2}$ in the weak advection regime.

## 4 Strong advection regime

We now determine the behavior of the system in the strong advection regime for $r \geq r_0$, where $r_0$ is the small constant from §3, or equivalently, for $\nu \geq \frac{R_0}{\delta \delta_0}$.

### 4.1 Slow-fast structure of the traveling front

We rescale $q = \frac{\delta}{r} \hat{q}$ and obtain
\[
\begin{align*}
 u_{\xi} &= p \\
p_{\xi} &= -cp - F(u, v) \\
v_{\xi} &= \varepsilon \hat{q} \\
\hat{q}_{\xi} &= r \left( - (1 + \varepsilon c) \hat{q} - G(u, v) \right),
\end{align*}
\]
where we recall \( \varepsilon := \nu^{-1} = \frac{\delta^2}{2} \). We now consider this equation in the regime \( 0 < \varepsilon \ll 1 \) and \( r \geq r_0 \). We use \( \varepsilon \) as the timescale separation parameter, so that \( v \) is a slow variable, and \((u, p, \tilde{q})\) are fast variables. We note that if \( r \) is large, then \( \tilde{q} \) evolves on a third ("super" fast) timescale; see below. Setting \( \varepsilon = 0 \) defines the layer problem

\[
\begin{aligned}
    u_\xi &= p \\
    p_\xi &= -cp - F(u, v) \\
    \tilde{q}_\xi &= -r(\tilde{q} + G(u, v)),
\end{aligned}
\]  

(4.2)

and the critical manifold

\[
\begin{aligned}
    \mathcal{M}_0 := \{ p = 0, F(u, v) = 0, \tilde{q} = -G(u, v) \},
\end{aligned}
\]  

(4.3)

which admits at least two normally hyperbolic branches \( \mathcal{M}_0^\pm = \{ p = 0, u = f^\pm(v), \tilde{q} = -G(f^\pm(v), v) \} \). The reduced flow on these manifolds is given by

\[
    v_\eta = -G(f^\pm(v), v)
\]  

(4.4)

with respect to \( \eta = \varepsilon \xi \). By Assumption 1, \( G_u(f^\pm(V^\pm))(f^\pm)'(V^\pm) + G_v(f^\pm(V^\pm), V^\pm) < 0 \), so that the equilibria \( v = V^\pm \) are repelling on \( \mathcal{M}_0^\pm \). We assume the following.

**Assumption 5.** Without loss of generality, we assume \( V^- > V^+ \) and that \( [V^+, V^-] \subseteq I_v \). Furthermore, \( G(f^-(v), v) < 0 \) for \( v \in [V^+, V^-] \).

In this case, the unstable manifold of the equilibrium \( v = V^- \) in the reduced flow (4.4) includes the segment \( \mathcal{M}_0^- \cap \{ V^+ \leq v < V^- \} \), consisting of a single solution; we denote by \( v = v^-(\eta) \) the corresponding solution satisfying \( v^-(0) = V^+ \). On the other hand, the stable manifold of \( v = V^+ \) in the reduced flow (4.4) on \( \mathcal{M}_0^+ \) is trivial; see Figure 4. Thus, to form a singular heteroclinic orbit between \( P^\pm \) in the full system, it is necessary for the fast jump to occur in the subspace \( v = V^+ \), which can be arranged by taking \( v_* = V^+ \), and choosing \( c_* \) appropriately to obtain a fast heteroclinic orbit \((u_*, p_*)(\xi)\) in the \((u, p)\)-subsystem of the layer problem

\[
\begin{aligned}
    u_\xi &= p \\
    p_\xi &= -cp - F(u, v_*).
\end{aligned}
\]  

(4.5)

The associated \( \tilde{q} \)-profile can then be obtained by integrating

\[
    \tilde{q}_*(\xi) = -r \int_{-\infty}^\xi e^{-r(\xi - \tilde{\xi})} G(u_*(\tilde{\xi}), v_*) d\tilde{\xi}.
\]  

(4.6)
We note that the additional fast direction adds a uniformly stable hyperbolic direction to each of the critical manifolds \( \hat{\mathcal{M}}_0^0, \hat{\mathcal{M}}_0^+ \), and hence just adds \(+1\) to the dimension of their respective stable manifolds. The resulting construction is valid for any value of \( r \) which is \( \mathcal{O}(1) \) with respect to \( \varepsilon \).

To make this construction well-defined in the limit \( r \to \infty \) (so that we obtain a slow-fast description of the traveling front for all \( r \geq r_0 \) and \( \varepsilon \leq \varepsilon_0 \) for some \( \varepsilon_0 \) independent of \( r \)), we note that for large \( r \gg 1 \), the system (4.1) is a slow-fast system with timescale separation parameter \( \rho := 1/r \), with one fast variable \( \tilde{q} \) and three slow variables \((u, p, v)\). For \( \rho = 0 \), the system admits a three-dimensional normally hyperbolic critical manifold

\[
Q_0 = \left\{ \tilde{q} = Q_0(u, p, v; \varepsilon) = -\frac{G(u, v)}{1 + \varepsilon c} \right\}
\]  

(4.7) which perturbs for all sufficiently small \( \rho > 0 \) to a normally hyperbolic slow manifold

\[
Q_\rho = \left\{ \tilde{q} = Q_\rho(u, p, v; \varepsilon) = -\frac{G(u, v)}{1 + \varepsilon c} + \mathcal{O}(\rho) \right\},
\]

(4.8) where we note that

\[
Q_\rho(f^\pm(v), 0, v; 0) = -G(f^\pm(v), v)
\]  

(4.9) for all \( \rho \) since when \( \varepsilon = 0 \), the sets \( \{(u, p, v, \tilde{q}) = (f^\pm(v), 0, v, -G(f^\pm(v), v))\} \) define curves of fixed points of (4.1). The flow on \( Q_\rho \) is given by

\[
\begin{align*}
  u_\varepsilon &= p \\
  p_\varepsilon &= -cp - F(u, v) \\
  v_\varepsilon &= \varepsilon Q_\rho(u, p, v; \varepsilon)
\end{align*}
\]  

(4.10) which is itself a slow-fast system with timescale separation parameter \( \varepsilon \). For \( \varepsilon = 0 \), this system admits critical manifolds which, in light of (4.9), are again given by \( \hat{\mathcal{M}}_0^\pm \) in the four-dimensional ambient space. The corresponding layer problem is given by (4.5), while the reduced problem on \( \hat{\mathcal{M}}_0^\pm \) is given by (4.4), again using (4.9). The construction of slow-fast traveling fronts in the full system (4.1) therefore proceeds similarly as above for all sufficiently small \( \varepsilon > 0 \), with the resulting orbits lying entirely within the invariant manifold \( Q_\rho \).

Putting together the results of this section, the slow-fast structure of traveling fronts is therefore well defined for any sufficiently small \( \varepsilon \), and any \( r \geq r_0 \). However, due to the relations between the parameters \( r, \delta, \varepsilon, \nu \), this region includes all \( \nu \geq \frac{\rho}{2\delta}, 0 < \delta \leq \delta_0 \), where the constant \( \delta_0 \) from §3 may be taken smaller, if necessary.

### 4.2 Long wavelength stability: leading-order computation of \( \lambda_{c,2} \)

We now consider the fronts from §4.1, using \( \varepsilon \) as the timescale separation parameter. We consider the fast

\[
\begin{align*}
  u_{\varepsilon\varepsilon} - cu_\varepsilon + F_u(u_h(\xi), v_h(\xi))u + G_u(u_h(\xi), v_h(\xi))v &= 0 \\
  \frac{1}{r} v_{\varepsilon\varepsilon} - (1 + \varepsilon c) v_\varepsilon + \varepsilon F_v(u_h(\xi), v_h(\xi))u + \varepsilon G_v(u_h(\xi), v_h(\xi))v &= 0
\end{align*}
\]  

(4.11) and slow

\[
\begin{align*}
  \varepsilon^2 u_{\eta\eta} - \varepsilon cu_\eta + F_u(u_h(\eta/\varepsilon), v_h(\eta/\varepsilon))u + G_u(u_h(\eta/\varepsilon), v_h(\eta/\varepsilon))v &= 0 \\
  \varepsilon v_{\eta\eta} - (1 + \varepsilon c) v_\eta + \varepsilon F_v(u_h(\eta/\varepsilon), v_h(\eta/\varepsilon))u + \varepsilon G_v(u_h(\eta/\varepsilon), v_h(\eta/\varepsilon))v &= 0
\end{align*}
\]  

(4.12) formulations of the adjoint equation, where \( \eta = \varepsilon \xi \). Proceeding as in §3.2.1, in the fast field, to leading order \( u_h(\xi) = u_*(\xi), v_h(\xi) = v_* \), and \( c = c_* \), so that \( v = \tilde{v}_* \) constant and \( u \) satisfies

\[
\begin{align*}
  u_{\varepsilon\varepsilon} - c_* u_\varepsilon + F_u(u_*(\xi), v_*)u &= -G_u(u_*(\xi), v_*)\tilde{v}_*,
\end{align*}
\]  

(4.13)
which implies that
\[ 0 = \bar{v}_s \int_{-\infty}^{\infty} G_u(u_s(\xi), v_s) u_s'(\xi) d\xi = \bar{v}_s \left( G(u_s^+, v_s) - G(u_s^-, v_s) \right), \]  
(4.14)
By Assumption 3, \( G(u_s^+, v_s) \neq G(u_s^-, v_s) \) so that \( \bar{v}_s = 0 \) to leading order, and \( u = \alpha_s u_s'(\xi)e^{c_s \xi} \). For the slow field, we recall that there is only a slow field along \( \mathcal{M}_0 \), on which \( v = v^- \) denotes the solution of (4.4) satisfying \( v^-(0) = V^+ \). Hence, to leading order, the adjoint equation reads
\[ F_u(f^-(v^-), v^-) u + G_u(f^-(v^-), v^-) v = 0 \]
(4.15)
\[-v_u + F_v(f^-(v^-), v^-) u + G_v(f^-(v^-), v^-) v = 0 \]
or equivalently
\[ -v_u + \left( G_v(f^-(v^-), v^-) - F_v(f^-(v^-), v^-) \right) = 0, \]
(4.16)
so that, in light of (4.4), to leading order \( v(\xi) = \alpha_0 v^-(\eta)^{-1} \) in the slow field, from which we deduce that \( \alpha_0 = 0 \) and hence \( v(\eta) = O(\varepsilon) \) in the slow field. Thus, we obtain (at leading order)
\[ \lambda_{c,2} = -\frac{\int_{-\infty}^{\infty} \alpha_s u_s'(\xi) e^{c_s \xi} d\xi}{\int_{-\infty}^{\infty} \alpha_s u_s'(\xi) e^{c_s \xi} d\xi} + O \left( \frac{\varepsilon}{\tau} \right) = -1 + O \left( \frac{\varepsilon}{\tau} \right), \]
which directly implies (2.18).

5 Application to a dryland ecosystem model

We apply the results of §3–4 to the following modified Klausmeier model [35] in the specific form introduced in [5]
\[ U_t = \Delta U - \mu_1 U + U^2 V (1 - \mu_2 U) \]
\[ V_t = \frac{1}{\delta^2} \Delta V + \mu_3 V - U^2 V + \nu V_x, \]
(5.1)
corresponding to (1.1) with \( \mu = (\mu_1, \mu_2, \mu_3) \) and
\[ F(U, V; \mu) = -\mu_1 U + U^2 V (1 - \mu_2 U), \]
\[ G(U, V; \mu) = \mu_3 V - U^2 V. \]
(5.2)
In the context of dryland ecosystem \( U \) represents biomass of a species of vegetation, while \( V \) represents a limiting resource such as water. The model (5.1) also corresponds to that considered in [22] in the case of a single species. The system parameters \( \mu_1, \mu_2, \mu_3 \) are positive and represent mortality, inverse of soil carrying capacity, and rainfall, respectively. The small parameter \( 0 < \delta \ll 1 \) representing the ratio of diffusion coefficients reflects the fact that water diffuses more quickly than vegetation, while the advection term \( \nu V_x \) models the downhill flow of water on a (constantly) sloped terrain, whose slope is oriented in the \( x \)-direction, with the coefficient \( \nu \) describing the grade of the slope. The primary differences between the model (5.1) and Klausmeier’s original model [35] are the inclusion of the large diffusion term in the water (\( V \)) equation, and the additional factor \( (1 - \mu_2 U) \) in the nonlinearity in the \( U \) equation, representing the carrying capacity of soil.

Remark 5.1. We note that Klausmeier’s original work [35] and many other studies [12, 23, 48] of the model (5.1) do not include the soil carrying capacity factor \( (1 - \mu_2 U) \) (i.e. the case \( \mu_2 = 0 \) representing infinite carrying capacity is considered). However, it is necessary to take \( \mu_2 > 0 \) here in order to apply the results of §2.3. This is due to the fact that the fast layer problem (2.5) associated with (5.1) is no longer bistable in the degenerate case \( \mu_2 = 0 \), which in turn means Assumption 1 cannot be satisfied.
Remark 5.2. In [5], the parameter $\nu$ was assumed large, which reflects the comparatively fast timescale on which water $V$ flows downhill (modeled via the advection term in the $u$ equation) compared to the rate at which the vegetation $U$ diffuses. It was shown in [5] in the absence of the diffusion term in the $V$ equation, i.e. in the limit $\delta \to \infty$ that stable planar vegetation fronts and stripes can form, aligned in the direction transverse to the slope of the terrain. Ecologically, one expects, however, that water does diffuse due to soil-water transport, and at a rate faster than that of vegetation [29], so that in fact one should include a large diffusion term in the $V$ equation, as in (5.1).

The system (5.1) was analyzed in the absence of advection, i.e. $\nu = 0$ in [14, §4.1], where it was shown that bistable interfaces are always unstable to long wavelength perturbations. Using the results of §§3–4, we show below that this same instability is present throughout the weak advection regime, but that the presence of sufficiently large ($\nu \gg 1$) advection can stabilize the fronts to long wavelength perturbations.

In (5.1), the set $S = \{F(U, V; \mu) = 0\}$ is comprised of three branches

\[
U = 0, \quad U = U^\pm(V) := \frac{1 \pm \sqrt{1 - \frac{4\mu_1\mu_2}{V}}}{2\mu_2}
\]  

(5.3)

where the latter two branches are defined in the region $V \geq 4\mu_1\mu_2$. To find steady states, we solve

\[
F(U, V; \mu) = G(U, V; \mu) = 0
\]

(5.4)

and deduce that (5.1) admits a stable steady state $(U^-, V^-) := (0, \mu_3)$ corresponding to zero vegetation (the ‘desert’ state). When

\[
\frac{\mu_3}{\mu_1} > 2\left(\mu_2 + \sqrt{1 + \mu_2^2}\right)
\]

(5.5)

there are two additional steady states $(U, V) = (U_{1,2}, V_{1,2})$ representing uniform vegetation where

\[
U_{1,2} = \frac{\mu_3 \pm \sqrt{\mu_3^2 - 4\mu_1(\mu_1 + \mu_2\mu_3)}}{2(\mu_1 + \mu_2\mu_3)}, \quad V_{1,2} = \mu_3 - \frac{\mu_1 U_{1,2}}{1 - \mu_2 U_{1,2}}.
\]

Furthermore, when

\[
\frac{\mu_3}{\mu_1} > 4\mu_2 + \frac{1}{\mu_2}
\]

(5.6)
the state \((U^+, V^+) := (U_2, V_2)\) is PDE stable, i.e. the condition 1(i) is satisfied, while the remaining steady state \((U_1, V_1)\) is always unstable \([5]\). Within the set \(\mathcal{S}\), the branches
\[
\mathcal{S}^- := \{ U = f^-(V) \equiv 0 \}, \quad \mathcal{S}^+ := \{ U = f^+(V) \equiv U_F^+(V) \},
\]
(5.7)
contain the steady states of interest: the state \((U^-, V^-)\) always lies on the branch \(\mathcal{S}^-\), and when (5.6) is satisfied, the state \((U^+, V^+)\) resides on \(\mathcal{S}^+\); see Figure 5. When considering bistable traveling fronts, we are therefore interested in fronts between the steady states \((U^-, V^-)\) and \((U^+, V^+)\) in the parameter regime (5.6) which traverse a singular heteroclinic orbit of the fast layer equation
\[
0 = U_{\xi \xi} + cU_\xi - \mu_1 U + U^2 V (1 - \mu_2 U)
\]
(5.8)
between the branches \(\mathcal{S}^-\) and \(\mathcal{S}^+\). We note that the cubic nonlinearity allows for the explicit construction of heteroclinic orbits in (5.8) between \(\mathcal{S}^-\) and \(\mathcal{S}^+\) for each \(v_\infty > 4\mu_1\mu_2\); see e.g. \([5, \S 2]\) or \([14, \S 4.1]\).

Using geometric singular perturbation techniques as in \([5]\), and separately considering the scalings in \(\S 3-4\), it is possible to rigorously construct bistable traveling fronts between \((U^\pm, V^\pm)\) in (5.1) for \(0 < \delta \ll 1\). Since we are primarily interested in the effect of advection on the stability of such interfaces, we do not carry out a detailed existence analysis here, but point to other works which rigorously construct traveling fronts and other traveling or stationary waves in various parameter regimes in the same equation (5.2): in particular, the condition (Assumption 5) necessary for existence in the strong advection regime is verified in \([5]\), while in the weak advection and intermediate regimes, Assumption 4 can be verified using similar techniques as in \([10]\). Therefore, in the remainder we assume the existence of a family of traveling fronts \(\phi \equiv (u_\infty, v_\infty)(\xi; \nu, \delta)\) for \(0 < \nu < \infty\) and sufficiently small \(\delta \ll 1\).

Figure 6 depicts the results of numerically continuing the coefficient \(\lambda_{c,2}\) in AUTO using the formula (2.14) along such a family of fronts for fixed \(\delta = 0.001\) and a wide range of \(\nu\) values. We now examine the behavior of the coefficient \(\lambda_{c,2}\) in the context of the asymptotic results of \(\S 3-4\). We evaluate
\[
F_* (u_\infty(\xi), v_\infty)e^{c_2 = (1- u_\infty(\xi))/\mu_2} > 0
\]
\[
G(u^+_\infty, v_\infty) - G(u^-_\infty, v_\infty) = -v_\infty(u^+_\infty)^2 < 0
\]
from which immediately deduce from (2.16) that \(F_* > 0\) and \(G_* < 0\). In particular, in the weak advection regime, this determines the sign of \(\lambda_{c,2}\) to be positive, and thus bistable planar fronts are always unstable to long wavelength perturbations in this regime. This agrees with the results of \([14, \S 4.1]\) in which the same equation was analyzed

\begin{figure}[h]
\centering
\begin{subfigure}{0.4\textwidth}
\centering
\includegraphics[width=\textwidth]{figure6a.png}
\caption{(a) Shown is a continuation branch of traveling front solutions of (5.1) over a range of \(\nu \in [0, 2 \cdot 10^4]\) for fixed \(\delta = 0.001\) and \(\mu = (0.1, 0.1, 2.0)\), computed in AUTO-07p. The coefficient \(\lambda_{c,2}\) is plotted versus \(\nu\). We observe that \(\lambda_{c,2}\) changes sign as \(\nu\) increases at \(\nu \approx 1472\), denoted by the red star. (b) Vertical zoom of the same plot as in (a), showing the horizontal asymptote \(\lambda_{c,2} = -1\).}
\end{subfigure}
\begin{subfigure}{0.4\textwidth}
\centering
\includegraphics[width=\textwidth]{figure6b.png}
\end{subfigure}
\end{figure}
in the absence of advection ($\nu = 0$). In the strong advection regime, based on the results of §4, we find that the coefficient $\lambda_{c,2}$ eventually changes sign as $\nu$ increases, so that suitably large advection therefore stabilizes the fronts to long wavelength perturbations. Comparing with Figure 6, which plots the coefficient $\lambda_{c,2}$ as a function of $\nu$, and we observe that its sign indeed changes upon increasing $\nu$ at $\nu \approx 1472$. We recall that the asymptotic results of §3.2.2 predict the change of sign to occur when $\nu \sim \delta^{-4/3}$. In Figure 7, we plot the results of continuing the equation $\lambda_{c,2} = 0$ in the parameters $\nu, \delta$. A log-log plot of $\nu$ versus $\delta$ demonstrates good agreement with the predicted $-4/3$ exponent. For larger values of $\nu$, we see in Figure 6 that $\lambda_{c,2}$ remains negative and approaches $-1$ as $\nu \to \infty$, which further agrees with the asymptotic predictions in the strong advection regime in §4.2.

6 Discussion

In this work, we examined the effect of advection on the stability of planar fronts in two spatial dimensions, motivated by observations of planar interfaces between desert and vegetated states in water limited ecosystems. In particular, we demonstrated a stabilizing mechanism of advection on a critical eigenvalue associated with long wavelength perturbations. In the context of application to dryland ecosystem models, this matches the common observation that interfaces between vegetation and bare soil present in vegetation patterns tend to align perpendicular to sloped terrain, on sufficiently steep slopes. The stability criteria posed in §2.3 are formulated for general systems, which allows for straightforward application of the results to a wide class of reaction-diffusion-advection models, under modest assumptions. We discuss some of the implications and limitations of the assumptions and results below, as well as some open problems.

While the results of §2.3 apply to a large class of models, we note that Assumption 1 limits the results to bistable traveling fronts. In particular, the results do not apply to the case of an invasion front into an unstable background state. The challenge is that one cannot as easily isolate instabilities associated with the interface of the front, due to the instability of the background state; in particular one can no longer infer stability properties of the front in two spatial dimensions by simply expanding the marginal translation eigenvalue associated with one-dimensional stability as in the current work. Typically such invasion fronts arise for an open range of wave speeds, with the selected wave speed resulting in either a pushed or pulled front, depending on whether the associated marginally stable spectrum is point or essential spectrum [2]. The subtle nature of these fronts makes even one-dimensional stability a challenging problem, which has recently been analyzed for general multicomponent reaction diffusion systems in [1].
Lastly, while the results presented here are of a formal asymptotic nature, we emphasize that they could be obtained rigorously using geometric singular perturbation techniques. In particular, in the strong advection regime \( \nu \geq O(\delta^{-2}) \) we expect it to be possible to show rigorously that the fronts described here (as well as multi-front stripe and periodic patterned solutions) are stable in two spatial dimensions by analyzing (2.6) for all values of \( \ell \in \mathbb{R} \) using a nearly
Figure 9 – Shown are the results of direct numerical simulations in (5.2) for $\delta = 0.01$ and $\mu = (1.2, 1.0, 6.2)$, performed similarly as those in Figure 8. The top row depicts the $U$-profile of the solution in the case $\nu = 500$ at times $t = \{5000, 10000, 15000, 20000\}$, while the bottom row depicts the solution in the case $\nu = 50$ at times $t = \{2000, 3000, 4000, 5000\}$. The critical stability boundary at which $\lambda_{c,2}$ changes sign was estimated at $\nu \approx 819$ for these parameter values. In the case $\nu = 500$ (top row) closer to the stability boundary, the same cusping behavior is observed as in Figure 8, while in the case $\nu = 50$ (bottom row) finger-like protrusions emerge on a comparatively shorter timescale.

identical approach as in [5, §5], via exponential dichotomies and the Lin–Sandstede method [11, 38, 46]. A rigorous treatment of the stability of such structures is the subject of future work.

A Stability of steady states

We briefly derive the conditions (2.4) of Assumption 1. Linearizing about the steady states $(U^\pm, V^\pm)$ of (1.1) and setting $(U, V)(x, y, t) = (U^\pm, V^\pm) + e^{\lambda t + ikx + iqy}(\bar{U}, \bar{V})$, we obtain the eigenvalue problem

$$
\lambda \begin{pmatrix} \bar{U} \\ \bar{V} \end{pmatrix} = \begin{pmatrix} -(k^2 + \ell^2) + F_u^\pm & F_v^\pm \\ G_u^\pm & -\frac{1}{\delta^2} (k^2 + \ell^2) + i\nu k + G_v^\pm \end{pmatrix} \begin{pmatrix} \bar{U} \\ \bar{V} \end{pmatrix}.
$$

(A.1)

The steady states $(U^\pm, V^\pm)$ are stable provided $\text{Re} \lambda(k, \ell) < 0$ for any eigenvalue $\lambda(k, \ell)$ of (A.1), or equivalently, any $\lambda(k, \ell)$ satisfying

$$
\lambda^2 + (p_1 + iq_1) \lambda + (p_2 + iq_2) = 0
$$

(A.2)

where

$$
p_1 = \left(1 + \frac{1}{\delta^2}\right)(k^2 + \ell^2) - F_u^\pm - G_v^\pm,
$$

$$
q_1 = -\nu k,
$$

$$
p_2 = F_u^\pm G_v^\pm - F_v^\pm G_u^\pm - \left(F_u^\pm G_v^\pm + G_u^\pm \right)(k^2 + \ell^2) + \frac{1}{\delta^2} (k^2 + \ell^2)^2 + \nu k F_u^\pm,
$$

$$
q_2 = -\nu k (k^2 + \ell^2) + \nu k F_u^\pm.
$$
The corresponding roots of this quadratic have strictly negative real part if and only if (see e.g. [26])

\[ p_1 > 0 \quad (A.3) \]
\[ p_1^2 p_2 + p_1 q_1 q_2 - q_2^2 > 0 \quad (A.4) \]

are satisfied for all \( k, \ell \in \mathbb{R} \). The condition \((A.3)\) implies that

\[ F_u^\pm + G_v^\pm < 0 \quad (A.5) \]

while \((A.4)\) implies (consider, e.g. \( k = \ell = 0 \))

\[ F_u^\pm G_v^\pm - F_v^\pm G_u^\pm > 0. \quad (A.6) \]

Considering \((A.4)\) for \( k = 0 \) and \( \ell = \mathcal{O}(\delta) \) implies that \( F_u^\pm < 0 \), while setting \( \ell = 0, k \ll 1 \) and \( \nu \) sufficiently large implies that \( G_v^\pm < 0 \) as well.
